---

In this paper, we investigate the impact of two-step Markov update scheme for the reinforcement component of XCS, a family of accuracy-based learning classifier systems. We use a mathematical framework using discrete-time dynamical system theory to analyze the stability and convergence of the proposed method. We provide frequency domain analysis for classifier parameters to investigate the achieved improvement of the XCS algorithm employing a two-step update rule in the transient and steady state stages of learning. An experimental analysis is performed to learn to solve a multiplexer benchmark problem to compare the results of the proposed update rules with the original XCS. The results show faster convergence, better steady state training accuracy, and less sensitivity to variations in learning rates.

---

## 1. Introduction

Learning Classifier Systems (LCSs) [1] are machine learning techniques, which use evolutionary computation and reinforcement learning in a supervised environment to model the system in the form of a population of “IF condition, THEN action” rules. LCSs started to become more popular after Wilson’s groundbreaking proposal, a simpler LCS structure with no message list and a new fitness calculation approach based on the classifier’s accuracy in predicting the environment payoff, namely XCS [2]. XCS employs a Q-learning [3] like update strategy and can work as a reinforcement learning or supervised learning framework. In XCS genetic algorithm favors the evolution of those classifiers that are maximally general and at the same time accurate in labeling problem instances. Genetic algorithm attempts to increase the number of classifiers with higher fitness by means of cross over and mutation.

Performance of XCS in data analysis applications has been investigated and proven to outperform some of the well-known machine learning approaches [4, 5]. A variety of studies have been done to even further simplify the structure of XCS and make them more appropriate for supervised learning problems such as UCS [6]. ExSTraCS is another class of LCSs that employs a specific rule representation scheme to store specified features in the classifier condition which helps to deal with problems with larger number of features [7]. XCSc is also proposed to address clustering problems using learning classifiers [8]. Moreover, Stolzmann introduced ACS [9], which is an anticipatory learning classifier system that is able to learn and predict current state and also next state of the problem and has been shown to perform well in problems such as learning a maze. In function approximation applications, XCSF [10, 11] is proposed that is able to learn an  $n$ -dimensional function using different approximations such as hyper-rectangles, hyper-ellipsoids and convex halls. Originally LCS was structured to model a Boolean environment, although later on numerous studies have been proposed to represent real-valued problems such as XCSR [12, 13] and problems with mixed attributes as in AKLR [14]. The robust bidding strategy of strength-based classifiers is studied in [15], and later in MLCS [16] is extended to handle multi-label data, while the labels are allowed to have confidence levels.

It has been shown that XCS is able to optimally solve Markov problems, whereas it suffers from handling non-Markov problems. Adding memory can help to overcome this problem through an internal register, which can store limited information about previous states. Systems that adopt memory include XCSM [17] and XCSMH [18]. In XCSM the internal bit-register is implemented directly instead of a list of messages however, in XCSMH a compound exploration is used in which the exploration strategy choose internal actions (register settings) deterministically, while selection of external actions remains probabilistic.

In XCS each classifier has a set of parameters which are updated in every cycle in which the classifier participates in learning. The XCS reinforcement module employs a Markov update scheme that uses only the current value of the parameter to calculate its future value. However classifiers interaction with its environment have non-Markov behavior in the sense that given the present attributes of the classifier, future values are not independent of the past. Therefore, it is useful to explicitly use agent's past parameter values in the update rule to improve estimates of parameter future values. Therefore, we initially focus on *extending current update rules of XCS parameters to an update rule with an additional history value*.

Moreover, we aim to address the current LCS literature's shortfall for analyzing interactions amongst classifier parameters in the algorithm. The lack of analysis tools affects our understanding of different

aspects of the problem such as algorithm stability, convergence and frequency domain analysis for performance investigation. Employing various mathematical tools provides better insight to the problem and future extensions of the algorithm.

This paper provides the following major contributions. First, the two-step Markov update scheme for the XCS algorithm is formulated to investigate its stability and convergence. Second, a frequency domain analysis of the discussed update scheme has been provided to investigate faster convergence and better steady state training accuracy. Since evolutionary-based machine learning algorithms are computationally more expensive than non-evolutionary approaches thus, reaching a reasonable accuracy threshold with less number of training iterations is crucial. Moreover, a mathematical framework using discrete-time dynamical system theory has been used to analyze the stability and convergence of two-step Markov update rules. Additionally, the sensitivity of the two-step update scheme to variations of learning rates is studied numerically.

## 2. XCS Classifier Overview

In this section, a brief description of the XCS algorithm is introduced. More details are provided in [2, 19, 20].

XCS acts as a reinforcement learning agent which receives inputs regarding the current state of the environment, reacts with actions and eventually receives a payoff as an indication of the effectiveness of its action. The goal of the XCS is to maximize the amount of payoff gathered in the long run.

The interaction of XCS with the environment is as follows. Once algorithm receives an input from the environment, it forms a match set  $[M]$  of all classifiers which have matching condition with the current input. The algorithm starts with empty population and covers for each input that there is no matching classifier in the population. For each unique action  $a$  in  $[M]$ , the prediction  $P(a)$  is computed, which is an estimate of the payoff that the learner expects from the system when action  $a$  is performed. Prediction array is calculated by the fitness-weighted average of all matching classifiers that support action  $a$  as

$$P_a = \frac{\sum_{cl \in [M] \wedge cl.a=a} p_{cl} F_{cl}}{\sum_{cl \in [M] \wedge cl.a=a} F_{cl}}, \quad (1)$$

where  $p$  is the prediction of each individual classifier  $cl$  and  $F$  is the classifier fitness.  $P_a$  forms a prediction array for different values of action  $a$ , and XCS selects the action with respect to the values in the prediction array, either by selecting maximum prediction or randomly selecting one from those suggested by classifiers in  $[M]$  [19].

After an action is selected, the action set  $[A]$  is created using the classifiers that advocate the selected action. After the action is performed, the prediction  $p$  and prediction error  $\varepsilon$  of all classifiers in  $[A]$  are updated through the following equations

$$p \leftarrow p + \beta(R - p), \quad (2)$$

$$\varepsilon \leftarrow \varepsilon + \beta(|R - p| - \varepsilon), \quad (3)$$

where  $\beta \in (0, 1]$  is the learning rate and  $R$  is the payoff received from the environment. Finally fitness  $F$  is updated toward the classifier's current relative accuracy  $\kappa'$  that is a function of classifier prediction error as follows

$$F \leftarrow F + \beta(\kappa' - F). \quad (4)$$

### 3. Introductory Review of Linear Discrete-time Dynamical Systems

As stated in the introduction section, the stability and convergence of the proposed two-step Markov update rules are investigated in the framework of discrete-time dynamical systems. For this purpose, we give a short description of some of the fundamental mathematical tools in this section, which are necessary for analyzing linear discrete-time dynamical systems. More details are provided in [21], [22], and [23].

#### 3.1 $z$ -Transform

A mathematical tool commonly used for the analysis of discrete-time dynamical systems is the  $z$ -transform. The role of the  $z$ -transform in discrete-time systems is similar to that of the Laplace transform in continuous-time systems.

The one-sided (unilateral)  $z$ -transform of a sequence  $x(t)$  where  $t$  takes zero or positive integers (i.e.  $x(t) = 0$  for all  $t < 0$ ) is defined as

$$x(z) = \mathcal{Z}\{x(t)\} = \sum_{t=0}^{\infty} x(t)z^{-t}, \quad (5)$$

where the symbol  $\mathcal{Z}$  denotes the  $z$ -transform of the term inside brackets. The equation (5) is, in general, an infinite sum or infinite power series, with  $z$  being a complex variable. For any given sequence, the set of values of  $z$  for which the  $z$ -transform converges is called the region of convergence (ROC). If  $x(z)$  is given as a rational function inside the ROC, i.e.

$$x(z) = \frac{p(z)}{q(z)}, \quad (6)$$

where  $p(z)$  and  $q(z)$  are polynomials in  $z$ , then the zeros are the roots of the numerator polynomial and the poles (for finite values of  $z$ ) are the roots of the denominator polynomial.

### ■ 3.2 Discrete-time Fourier Transform

An other mathematical tool commonly used for the analysis of discrete-time dynamical systems is the discrete-time Fourier transform. The discrete-time Fourier transform of a sequence  $x(t)$  where  $t$  takes zero or positive integers (i.e.  $x(t) = 0$  for all  $t < 0$ ) is defined as

$$x(e^{j\omega}) = \sum_{t=0}^{\infty} x(t)e^{-j\omega t}, \quad (7)$$

with  $\omega$  being a real number ranging over an interval of length  $2\pi$  and  $j \triangleq \sqrt{-1}$ . In particular, if we replace the complex variable  $z$  in equation (5) with the complex variable  $e^{j\omega}$ , then the  $z$ -transform reduces to the Fourier transform. This is one motivation for the notation  $x(e^{j\omega})$  for the Fourier transform; when it *exists*, the Fourier transform is simply  $x(z)$  with  $z = e^{j\omega}$ . Mathematically it means that the Fourier transform of  $x(t)$  converges absolutely if and only if the ROC of the  $z$ -transform of  $x(t)$  includes the unit circle.

### ■ 3.3 Initial Value Theorem

If  $x(t)$  has the  $z$ -transform  $x(z)$  and if  $\lim_{z \rightarrow \infty} x(z)$  exists, then the initial value  $x(0)$  of  $x(t)$  is given by

$$x(0) = \lim_{z \rightarrow \infty} x(z). \quad (8)$$

Basically, this theorem relates frequency domain analysis to the time domain behavior as time approaches zero.

### ■ 3.4 Final Value Theorem

If  $x(t)$  has the  $z$ -transform  $x(z)$  and all the poles of  $x(z)$  lie inside the unit circle, with the possible exception of a pole of order one at  $z = 1$ , then the final value of  $x(t)$ , that is, the value of  $x(t)$  as  $t$  approaches infinity, is given by

$$\lim_{t \rightarrow \infty} x(t) = \lim_{z \rightarrow 1} [(z - 1)x(z)]. \quad (9)$$

In contrast to the initial value theorem, the final value theorem relates frequency domain analysis to the time domain behavior as time approaches infinity.

### ■ 3.5 Linear Discrete-time Dynamical System

The  $z$ -transform is particularly useful in the analysis of linear time-invariant (LTI) systems described by the difference equations. Consider

the  $n$ -th order LTI discrete-time system characterized by the following linear difference equation

$$y(t) + a_1y(t-1) + \cdots + a_ny(t-n) = b_0u(t) + b_1u(t-1) + \cdots + b_nu(t-n), \quad (10)$$

where  $u(t)$  and  $y(t)$  are the system's input and output, respectively, at the  $t$ -th time step. Note that some of the coefficients  $a_i$  and  $b_j$  may be zero. By taking the  $z$ -transform of equation (10), the system transfer function is given by

$$H(z) \triangleq \frac{y(z)}{u(z)} = \frac{b_0z^n + b_1z^{n-1} + \cdots + b_n}{z^n + a_1z^{n-1} + \cdots + a_n}. \quad (11)$$

### ■ 3.6 Lyapunov Stability

Consider the discrete-time system with the state equation

$$\mathbf{x}(t+1) = \mathbf{f}(\mathbf{x}(t), \mathbf{u}(t)), \quad (12)$$

where  $\mathbf{x} \in \mathbb{R}^n$ ,  $\mathbf{u} \in \mathbb{R}^m$ , and  $\mathbf{f} \in \mathbb{R}^n$  with the property that  $\mathbf{f}(\mathbf{0}, \mathbf{0}) = \mathbf{0}$ . An equilibrium point  $\mathbf{x} = \mathbf{0}$  of the unforced (zero input) dynamical system

$$\mathbf{x}(t+1) = \mathbf{f}(\mathbf{x}(t), \mathbf{0}), \quad (13)$$

is called globally uniformly asymptotically stable (GUAS); if it is stable (in the Lyapunov sense) and every solution converges to zero as  $t$  goes to infinity, i.e.  $\lim_{t \rightarrow \infty} \|\mathbf{x}(t)\| = \mathbf{0}$ .

If the unforced system (13) has a GUAS equilibrium point at the origin  $\mathbf{x} = \mathbf{0}$ , then we are interested in whether a bounded input  $\mathbf{u}(t)$  implies that the state  $\mathbf{x}(t)$  is bounded too. This is the notion of input-to-state stability. It is shown in [21] that if the unforced system (13) has a GUAS equilibrium point at the origin  $\mathbf{x} = \mathbf{0}$ , then the system (12) is input-to-state stable.

There are many ways to realize state-space representations for the LTI discrete-time system described by equation (10) or (11) as

$$\begin{aligned} \mathbf{x}(t+1) &= \mathbf{G}\mathbf{x}(t) + \mathbf{H}\mathbf{u}(t), \\ \mathbf{y}(t) &= \mathbf{C}\mathbf{x}(t) + \mathbf{D}\mathbf{u}(t), \end{aligned} \quad (14)$$

where  $\mathbf{x} \in \mathbb{R}^n$ ,  $\mathbf{u} \in \mathbb{R}^m$ ,  $\mathbf{y} \in \mathbb{R}^r$  and  $\mathbf{G}$ ,  $\mathbf{H}$ ,  $\mathbf{C}$  and  $\mathbf{D}$  are known matrices with compatible dimension. The origin  $\mathbf{x} = \mathbf{0}$  of the unforced system

$$\mathbf{x}(t+1) = \mathbf{G}\mathbf{x}(t), \quad (15)$$

is GUAS if and only if all eigenvalues of  $\mathbf{G}$  has magnitude less than 1, i.e.  $|\lambda_i(\mathbf{G})| < 1$ . Since the characteristic equation which is the determinant of  $|z\mathbf{I} - \mathbf{G}|$  can be written as

$$\Delta(z) \triangleq |z\mathbf{I} - \mathbf{G}| = z^n + a_1 z^{n-1} + \cdots + a_n, \quad (16)$$

therefore, the origin  $\mathbf{x} = \mathbf{0}$  of the unforced system (15) is GUAS if and only if the poles of the system transfer function (11) lie inside the unit circle in the  $z$  plane.

### ■ 3.7 Jury Stability Test

The Jury stability test can be applied directly to the characteristic equation  $\Delta(z) = 0$  without solving for the roots. The test reveal the existence of any unstable roots, i.e. the roots that lie outside the unit circle in the  $z$  plane.

## ■ 4. XCS with Two-Step Markov Update Algorithm

---

### ■ 4.1 Reinforcement Component

In this section the two-step Markov update scheme for the reinforcement component of the XCS is formulated based on the fact that when the present value of the classifier is known, then its future value is not independent of the past (non-Markov); and past information (observations) can be explicitly used in the classifier update process to achieve better predictions of future values. One can increase a two-step Markov update to a  $n$ -step Markov update in general. Note that only the classifier parameters in the action set  $[A]$  are updated, i.e. whenever a classifier participates in an action set, its prediction, prediction error, and fitness are updated based on the weighted sum of its present and its one step previous values. The weights are controlled by different learning rates  $\beta$  and  $\eta$ .

In XCS, the Q-learning reinforcement module [3] is restated as a difference equation in which present values are used to calculate future values of the parameters. Therefore, classifier prediction  $p(t)$  and prediction error  $\varepsilon(t)$  are updated through the following modified difference equations in which the update arrow is replaced with equality sign to better serve the purpose of discrete-time analysis. The convergence of the two-step update rule is guaranteed by choosing the proper learning rates as derived in section 4.2.

$$p(t+1) = p(t) + \beta \left( \frac{\beta + \eta - 1}{\beta} R - p(t) \right) + (1 - \eta)p(t-1), \quad (17)$$

$$\varepsilon(t+1) = \varepsilon(t) + \beta(|R - p(t)| - \varepsilon(t)) + (1 - \eta)\varepsilon(t-1), \quad (18)$$

for all iterations  $t \geq 0$ , initial conditions  $p(0) = p(-1) = 0$  and  $\varepsilon(0) = \varepsilon(-1) = 0$  where  $\beta \in (1 - \eta, 1]$  is the one-step learning rate,  $\eta \in (0, 1]$  denotes the two-step learning rate and  $R$  is the payoff received from the environment. Note that in (17), the coefficient of  $R$  is adapted to guarantee the asymptotic convergence of the prediction  $p(t)$  to  $R$  when the model is completely trained. This is shown in the proof of Lemma 1.

To update the classifier fitness  $F(t)$ , the classifier accuracy  $\kappa(t)$  and the classifier relative accuracy  $\kappa'(t)$  are computed as in the XCS algorithm [24] as shown below

$$\kappa(t) = \begin{cases} 1, & \text{if } \varepsilon(t) < \varepsilon_0 \\ \alpha \left( \frac{\varepsilon(t)}{\varepsilon_0} \right)^{-\nu}, & \text{otherwise} \end{cases}$$

$$\kappa'(t) = \frac{\kappa(t) \cdot \text{num}(t)}{\sum_{cl \in [A]} \kappa_{cl}(t) \cdot \text{num}_{cl}(t)}. \quad (19)$$

The parameter  $\varepsilon_0 > 0$  controls the prediction error tolerance; the parameters  $0 < \alpha < 1$ ,  $\nu > 0$  are constants and “num” is the number of copies of the classifier being updated. Finally, classifier fitness  $F(t)$  is updated toward the classifier’s current relative accuracy  $\kappa'(t)$  through the following modified difference equation

$$F(t+1) = F(t) + \beta \left( \frac{\beta + \eta - 1}{\beta} \kappa'(t) - F(t) \right) + (1 - \eta)F(t-1), \quad (20)$$

for all iterations  $t \geq 0$  and initial conditions  $F(0) = F(-1) = 0$ . Note that in (20), the coefficient of  $\kappa'(t)$  is adapted to guarantee the asymptotic convergence of the fitness  $F(t)$  to 1 when the model is completely trained.

**Corollary 1.**  $1 - \beta$  and  $1 - \eta$  are the weights of present and previous values in the two-step Markov update equations (17), (18), and (20). By changing  $\eta$  continuously from  $0^+$  to 1, one can observe the entire spectrum of the algorithm behavior from pure previous value to pure present value update. As  $\eta$  approaches to 1, the algorithm acts like the original XCS and vice versa. When  $\beta < \eta$ , more weight is given to the present than previous values and vice versa. If  $\eta \in (\frac{1}{2}, 1]$ , then there always exists  $\beta \in (1 - \eta, 1]$  such that  $\beta = \eta$ , i.e. we have equal weights for the present and previous values.

#### ■ 4.2 Stability and Convergence Analysis

In this section the set of classifier parameters are analyzed for stability and convergence of the learning algorithm, i.e. difference equations (17), (18), and (20). By finding a proper range for learning rates  $\beta$  and  $\eta$ , we have shown that the proposed two-step Markov update algorithm is GUAS; hence the stability and convergence of the algorithm is guaranteed.

Defining a new variable  $q(t) \triangleq R - p(t)$  with initial conditions  $q(0) = q(-1) = R$ , the equations (17) and (18) can be rewritten as

$$q(t+1) = (1 - \beta)q(t) + (1 - \eta)q(t-1), \quad (21)$$

$$\varepsilon(t+1) = (1 - \beta)\varepsilon(t) + (1 - \eta)\varepsilon(t-1) + \beta|q(t)|, \quad (22)$$

which is a discrete-time cascade<sup>1</sup> dynamical system and has an equilibrium point at  $(q, \varepsilon) = (0, 0)$ . To show that the equilibrium point of the set of equations (21) and (22) is GUAS, the following lemma is introduced.

**Lemma 1.** If the system (22), with  $q(t)$  as its input, is input-to-state stable and the system (21) has a GUAS equilibrium point at the origin  $q = 0$ , then the cascade dynamical system (21) and (22) has a GUAS equilibrium point at the origin  $(q, \varepsilon) = (0, 0)$ .

*Proof.* Taking the  $z$ -transform of equation (21) with the initial condition  $q(0) = R$  leads to

$$q(z) = \frac{Rz^2}{z^2 - (1 - \beta)z - (1 - \eta)}. \quad (23)$$

The system (21) has a GUAS equilibrium point at its origin  $q = 0$  if and only if the characteristic equation

$$\Delta(z) = z^2 - (1 - \beta)z - (1 - \eta), \quad (24)$$

is stable, i.e. all the poles of  $q(z)$  lie within the unit circle in the  $z$  plane. The Jury stability test is applied to determine the stability of the characteristic equation (24) without solving for the roots. Therefore, the following conditions must be satisfied

$$\begin{aligned} |1 - \eta| < 1 &\Rightarrow 0 < \eta < 2 \\ \beta + \eta - 1 > 0 &\Rightarrow \beta > 1 - \eta \\ -\beta + \eta + 1 > 0 &\Rightarrow \beta < 1 + \eta \end{aligned} \quad (25)$$

<sup>1</sup>The set of dynamical systems (21) and (22) is called cascade since (21) does not depend on  $\varepsilon(t)$  and the output of (21), i.e.  $q(t)$  is fed as an input to (22).

In addition to these three conditions, two additional sufficient conditions are imposed by the non-negativity of present and previous updating weights on the states of the system to make sure the prediction, prediction error, and fitness values are all non-negative for all  $t$ , as in the following

$$\eta \leq 1 \quad \text{and} \quad \beta \leq 1. \quad (26)$$

Considering the inequalities (25) and (26) together implies that

$$0 < \eta \leq 1 \quad \text{and} \quad 1 - \eta < \beta \leq 1. \quad (27)$$

From the global asymptotic stability of the origin of the system (21), it is concluded that

$$\lim_{t \rightarrow \infty} q(t) = 0 \quad \Rightarrow \quad \lim_{t \rightarrow \infty} p(t) = R, \quad (28)$$

which shows that the classifier prediction  $p(t)$  is bounded for all  $t$  and globally asymptotically converges to  $R$ .

In order to show that (22) is input-to-state stable, it is required that the unforced system

$$\varepsilon(t+1) = (1-\beta)\varepsilon(t) + (1-\eta)\varepsilon(t-1), \quad (29)$$

has a GUAS equilibrium point at its origin  $\varepsilon = 0$ , which is equivalent to having the same stable characteristic equation as (24). Hence, choosing the learning rates as in (27) ensures that (22) is input-to-state stable. Therefore using the fact that the origin of system (21) is GUAS, we conclude that the origin of system (22), which is  $\varepsilon = 0$ , is also GUAS, i.e.  $\lim_{t \rightarrow \infty} \varepsilon(t) = 0$ . This proves that the classifier prediction error  $\varepsilon(t)$  is bounded for all  $t$  and globally asymptotically converges to zero. This concludes the proof of Lemma 1.  $\square$

**Corollary 2.** Satisfying the learning rates  $\beta$  and  $\eta$  in (27) forces both poles of the characteristic equation (24) to be always inside the unit circle. Furthermore, the poles always appear as one having positive real root ( $r_+ \geq 0$ ) and one negative real root ( $r_- \leq 0$ ) as  $(1-\beta)^2 + 4(1-\eta) \geq (1-\beta)^2$  for every  $\beta$  and  $\eta$  in (27). From characteristic equation (24) we have

$$\begin{aligned} r_+ &= \frac{1-\beta + \sqrt{(1-\beta)^2 + 4(1-\eta)}}{2}, \\ r_- &= \frac{1-\beta - \sqrt{(1-\beta)^2 + 4(1-\eta)}}{2}. \end{aligned} \quad (30)$$

Also, (27) implies that

$$0 \leq 1 - \eta < \beta \leq 1 \quad \Rightarrow \quad 1 - \beta \leq \sqrt{(1-\beta)^2 + 4(1-\eta)} < 1 + \beta. \quad (31)$$

Combining equations (30) and (31), we have

$$-1 \leq -\beta < r_- \leq 0 \leq 1 - \beta \leq r_+ < 1. \quad (32)$$

In the case of  $\eta = 1$ , i.e.  $r_- = 0$ ,  $r_+ = 1 - \beta$ , the characteristic equation (24) would be a first order characteristic equation with a single pole at  $z = 1 - \beta$  as there is a pole zero cancellation in (23) at  $z = 0$ , which is the original one step XCS.

**Corollary 3.** As explained in corollary 2, the classifier prediction update equation (17) is a second order system with two real distinct poles  $r_+$  and  $r_-$  inside the unit circle. This system is called overdamped, i.e. the response  $p(t)$  is smooth and non-oscillatory and asymptotically follows the payoff  $R$ . Therefore, for every  $t$  there are

$$p(t) \leq R \quad \Rightarrow \quad R - p(t) \geq 0. \quad (33)$$

As a result  $|R - p(t)|$  that originally is introduced in XCS update rule can be replaced with  $R - p(t)$  in the prediction error update equation (18). The same reasoning applies to one step prediction as in equation (3), which is a stable first order system that never oscillates.

An obvious challenge for such an evolving, distributed knowledge representation is the continuous support of all problem subspaces which is identified as niche support. In XCS niche support is guaranteed by a niche-based deletion method plus an occurrence-based reproduction method. It is shown in [25], assuming a Markov chain model for niche support, population is distributed according to a binomial distribution over all niches of the problem in steady state. It concludes that at steady state, equation (19) results in

$$\lim_{t \rightarrow \infty} \kappa'(t) = 1. \quad (34)$$

The relative accuracy  $\kappa'(t)$  given in (19) is also bounded by  $0 \leq \kappa'(t) \leq 1$  with  $\kappa'(0) \neq 0$  as  $\kappa(0) = 1$  due to initialization of  $\varepsilon(0) = 0$ . Using the final value theorem, (34) implies that  $\kappa'(z)$  can be decomposed as

$$\mathcal{Z}\{\kappa'(t)\} = \kappa'(z) = \frac{1}{z-1} \cdot \frac{b(z)}{d(z)}, \quad (35)$$

where  $b(z)$  and  $d(z)$  are polynomials in  $z$  with no factor of  $(z-1)$ . Using the initial value theorem, we also have

$$\kappa'(0) \neq 0 \Rightarrow \lim_{z \rightarrow \infty} \kappa'(z) = \lim_{z \rightarrow \infty} \frac{1}{z-1} \cdot \frac{b(z)}{d(z)} \neq 0, \quad (36)$$

where  $\frac{b(z)}{d(z)}$  is a stable rational transfer function which satisfies the following degree condition

$$\deg(b(z)) = \deg(d(z)) + 1. \quad (37)$$

Since  $\kappa'(z)$  satisfies the conditions of the final value theorem as all of its poles lie inside the unit circle with a pole of order one at  $z = 1$ , we conclude that

$$1 = \lim_{t \rightarrow \infty} \kappa'(t) = \lim_{z \rightarrow 1} (z - 1)\kappa'(z) = \frac{b(1)}{d(1)}. \quad (38)$$

The analysis of relative accuracy will shed light on the convergence of classifier fitness. To show that classifier fitness  $F(t)$  is updated toward the classifier's current relative accuracy  $\kappa'(t)$ , equation (20) is rewritten as

$$F(t + 1) = (1 - \beta)F(t) + (1 - \eta)F(t - 1) + (\beta + \eta - 1)\kappa'(t), \quad (39)$$

which is input-to-state stable with  $\kappa'(t)$  as its input because the unforced system (39) has the same characteristic equation as (24). Taking the  $z$ -transform of (39) with the initial condition  $F(0) = 0$  yields

$$F(z) = \frac{(\beta + \eta - 1)z}{z^2 - (1 - \beta)z - (1 - \eta)} \cdot \kappa'(z). \quad (40)$$

From (27) and (35) it can be concluded that  $F(z)$  satisfies the conditions of the final value theorem. Consequently we have

$$\lim_{t \rightarrow \infty} F(t) = \lim_{z \rightarrow 1} (z - 1)F(z) = \lim_{z \rightarrow 1} (z - 1)\kappa'(z) = \lim_{t \rightarrow \infty} \kappa'(t) = 1. \quad (41)$$

Therefore, the classifier fitness  $F(t)$  is also bounded for all  $t$  and globally asymptotically converges to 1.

#### ■ 4.3 Frequency Domain Analysis

In order to gain a better understanding of the impact of modified reinforcement component of the XCS on the dynamic of overall algorithm, in this section the frequency responses of the transfer functions between the input payoff “ $R$ ” and the output prediction error “ $\varepsilon(t)$ ” are studied. In particular, this analysis will provide a clear understanding of the transient behavior and the steady state accuracy of the proposed algorithm. For the proposed two-step and the original XCS update algorithms, here parameters are denoted by the subscripts “2 - step” and “1 - step” respectively.

**Lemma 2.** The two-step update scheme has a faster prediction error convergence rate in the transient and better steady state accuracy compare to the original XCS.

*Proof.* The prediction and prediction error update equations for the one step update scheme are given by

$$\begin{aligned} p_{1-step}(t + 1) &= (1 - \beta)p_{1-step}(t) + \beta R, \\ \varepsilon_{1-step}(t + 1) &= (1 - \beta)\varepsilon_{1-step}(t) - \beta p_{1-step}(t) + \beta R, \end{aligned} \quad (42)$$

which is a linear discrete-time cascade dynamical system. The transfer function from the input payoff “ $R$ ” to the output prediction error “ $\varepsilon_{1\text{-step}}(t)$ ” is given by

$$H_{1\text{-step}}(z) \triangleq \frac{\varepsilon_{1\text{-step}}(z)}{R(z)} = \frac{\beta(z-1)}{(z-(1-\beta))^2}. \quad (43)$$

Similarly, (17) and (18) together is also a linear discrete-time cascade dynamical system of the proposed method and the transfer function from the input payoff “ $R$ ” to the output prediction error “ $\varepsilon_{2\text{-step}}(t)$ ” is given by

$$H_{2\text{-step}}(z) \triangleq \frac{\varepsilon_{2\text{-step}}(z)}{R(z)} = \frac{\beta z(z-1)(z+1-\eta)}{(z^2-(1-\beta)z-(1-\eta))^2}. \quad (44)$$

To compare the two transfer functions (43) and (44), we first need to define their ratio as

$$H(z) \triangleq \frac{H_{2\text{-step}}(z)}{H_{1\text{-step}}(z)} = \frac{\varepsilon_{2\text{-step}}(z)}{\varepsilon_{1\text{-step}}(z)} = \frac{z(z+1-\eta)(z-1+\beta)^2}{(z^2-(1-\beta)z-(1-\eta))^2}. \quad (45)$$

Clearly for  $\eta = 1$ , the ratio in (45) is always one regardless of the value of  $\beta$ .

Since (45) is a stable rational system transfer function, its ROC includes the unit circle. Therefore, if we replace the complex variable  $z$  in (45) with the complex quantity  $e^{j\omega}$ , then the  $z$ -transform reduces to the Fourier transform.

Next, we show that the two-step update scheme has a faster convergence rate in the transient and better steady state accuracy compared to the original XCS. First, we need to show that the amplitude of the Fourier transform of (44) is greater than (43) or equivalently, the amplitude of Fourier transform of (45) is greater than one over the low frequency range, i.e.  $\omega$  around 0, and the high frequency range, i.e.  $\omega$  around  $\pm\pi$ . For the low frequency range, we have

$$\lim_{\omega \rightarrow 0} |H(e^{j\omega})| = \lim_{z \rightarrow 1} |H(z)| = \frac{\beta^2(2-\eta)}{(\beta+\eta-1)^2} \geq 1, \quad (46)$$

where the inequality is satisfied with the equality holding only for  $\eta = 1$ .

The inequality in (46) is satisfied because according to (27),  $2-\eta \geq 1$  and

$$\begin{aligned} 0 \leq 1-\eta < \beta \leq 1 &\Rightarrow 0 \leq \frac{1-\eta}{\beta} < 1 \Rightarrow 0 < 1 - \frac{1-\eta}{\beta} \leq 1 \\ &\Rightarrow \frac{\beta}{\beta+\eta-1} \geq 1 \Rightarrow \frac{\beta^2(2-\eta)}{(\beta+\eta-1)^2} \geq 1. \end{aligned} \quad (47)$$

Similarly, for the high frequency range we have

$$\lim_{\omega \rightarrow \pm\pi} |H(e^{j\omega})| = \lim_{z \rightarrow -1} |H(z)| = \frac{\eta(2-\beta)^2}{(1-\beta+\eta)^2} \geq 1, \quad (48)$$

where the inequality is satisfied with the equality holding only for  $\eta = 1$ .

To show that the inequality in (48) is satisfied, we know from (27)

$$0 \leq 1 - \beta < \eta \quad \text{and} \quad 1 - \eta \geq 0 \quad \text{and} \quad \eta^2 \leq \eta. \quad (49)$$

Then,

$$\begin{aligned} (1-\beta)^2 &< \eta^2 \leq \eta \\ \Rightarrow (1-\eta)((1-\beta)^2 - \eta) &\leq 0 \\ \Rightarrow (1-\eta)(\beta^2 - 2\beta) + (1-\eta)^2 &\leq 0 \\ \Rightarrow 1 + \beta^2 + \eta^2 - 2\beta + 2\eta - 2\beta\eta &\leq 4\eta - 4\eta\beta + \eta\beta^2 \\ \Rightarrow (1-\beta+\eta)^2 &\leq \eta(2-\beta)^2 \\ \Rightarrow \frac{\eta(2-\beta)^2}{(1-\beta+\eta)^2} &\geq 1. \end{aligned} \quad (50)$$

This concludes the proof of Lemma 2.  $\square$

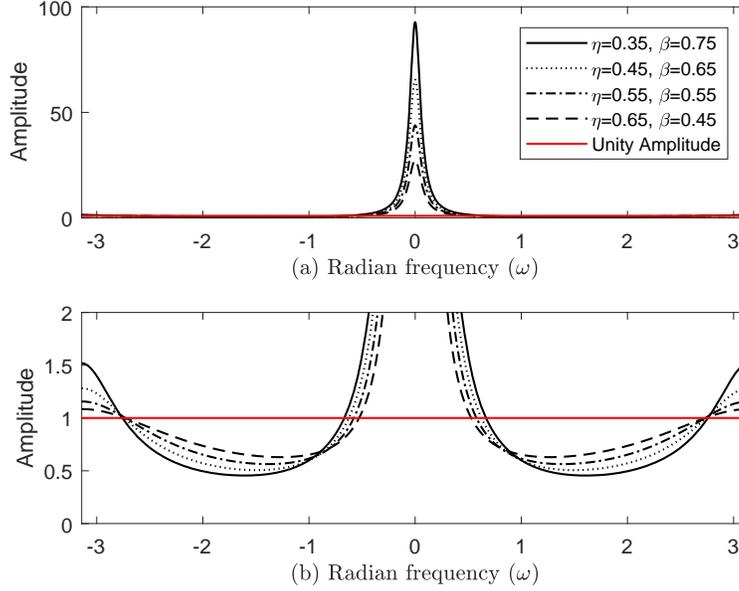

The overall accuracy of the XCS model is a function of its individual rule's prediction error therefore, the two-step update XCS algorithm has a faster convergence and better steady state accuracy. Fig. 1: (a, b) is the amplitude plot of Fourier transform of (45), i.e.

$$|H(e^{j\omega})| = \frac{|H_{2\text{-step}}(e^{j\omega})|}{|H_{1\text{-step}}(e^{j\omega})|} = \left| \frac{z(z+1-\eta)(z-1+\beta)^2}{(z^2 - (1-\beta)z - (1-\eta))^2} \right|_{z=e^{j\omega}}, \quad (51)$$

for the range of  $\omega$  between  $-\pi$  and  $\pi$  for some values of  $\eta$  and  $\beta$ , which shows how the amplitudes vary over this frequency range. Fig. 1: (a) is magnified around unity amplitude and is plotted in Fig. 1: (b) for better illustration. As we have shown in Lemma 2, the two-step update scheme has a faster convergence rate over the high frequency range, i.e.  $\omega$  around  $\pm\pi$  and better steady state accuracy over the low frequency range, i.e.  $\omega$  around 0, as implied by  $|H(e^{j\omega})|$  which is greater than one.

## 5. Numerical Results and Discussion

In this section, to investigate the effect of the proposed two-step update scheme compared to the original one-step update, the XCS algorithm is trained to solve the multiplexer problem. For this purpose, three multiplexer problems, i.e. 6-MUX, 11-MUX, and 20-MUX are solved.

**Figure 1.** (a)  $|H(e^{j\omega})|$  (b) Magnified plot (a) around unity amplitude.

The common parameters used for all the problems are  $\alpha = 0.1$ ,  $\varepsilon_0 = 0.0001$ ,  $\nu = 25$ ,  $\mu = 0.04$ ,  $R = 1000$ , and probability of specifying an attribute is equal to 0.5 [24]. Finally, frequency of applying GA is 10 and tournament selection is used for reproduction. Population size ( $N$ ) and crossover probability ( $\chi$ ) are specified for each experiment later in the problem.  $\beta$  and  $\eta$  are selected according to equation (27) to observe variations in the results.

Due to the stochastic nature of the algorithm, to have a reliable result, the model needs to be trained multiple times and accuracy averaged over trained models. We define the empirical mean  $\bar{X}$  of  $m$  runs that form a collection of  $m$  random variables  $X_1, \dots, X_m$ , which are independent and identically distributed (i.i.d.) and bounded by the interval  $[0, 1]$ . The empirical mean is given as

$$\bar{X} = \frac{X_1 + \dots + X_m}{m}. \quad (52)$$

If we choose

$$m \geq \frac{\ln \frac{2}{\lambda}}{2\sigma^2}, \quad (53)$$

through the Hoeffding's inequality [26], then with probability at least  $1 - \lambda$ , the difference between the empirical mean  $\bar{X}$  and the true mean

$E[\bar{X}]$  is at most  $\sigma$ , where  $E[\cdot]$  denotes the mathematical expected value of its argument. The  $\sigma$  says how far we are willing to allow the empirical mean to be from the true mean and the  $\lambda$  says with what probability we are willing to allow a deviation larger than  $\sigma$ . For a given  $\lambda = 0.10$  and  $\sigma = 0.15$  in (53), we have  $m \geq 66$  therefore, simulation results are averaged over 66 runs.

In the literature, value of  $\beta$  is selected to be 0.2 [25, 27], yet it is worthwhile to investigate how the algorithm will behave with different learning rates. The accuracy is computed as the percentage of correct classifications

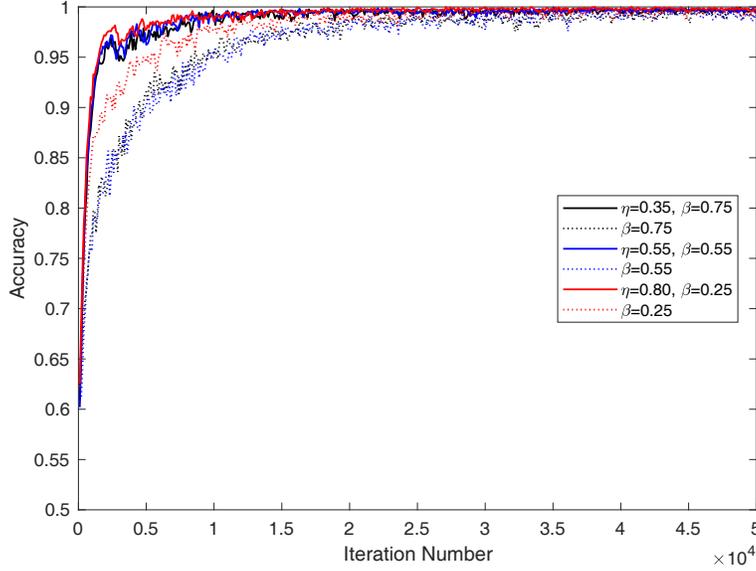

$$\text{accuracy} = \frac{\text{number of correct classifications}}{\text{number of covered instances}}. \quad (54)$$

In the first experiment, three different combinations of  $\beta$  and  $\eta$  are selected and the training accuracy of algorithm is plotted in Fig. 2 for both update rules. As expected from the weighted sum of the current and previous values in two-step update, the result shows that the two-step update rule is less sensitive to variations in learning rates  $\beta$  and  $\eta$ , and has a faster convergence rate in the transient and steady state, while in the one-step approach the training accuracy deteriorates as  $\beta$  increases. Nonetheless, the final training accuracies are almost equal for both updates.

To elaborate more on the effects of the proposed update rules, using information from one extra step back in time acts like a lag-lead compensator in conventional control theory, which helps to have faster convergence and better steady state accuracy. In other words, adding memory will help to generate a better estimate of future classifier parameters specifically when the present value of parameters are experiencing undesired variations for partially correct classifiers. Partially correct classifiers refer to relatively general classifiers that can match more problem instances, which do not necessarily classify correctly.

Experiments on 11-MUX and 20-MUX problems as demonstrated in Figs. 3 and 4, also confirm the improvement in the rate at which algorithm learns the problem. The results show that the two-step update rule is less sensitive to variations in  $\beta$  and  $\eta$ , has a faster convergence rate in the transient and steady state, and achieves better training accuracy specifically for the 20-MUX problem. The only exception in these results corresponds to  $\beta = 0.25$  for one-step update in 11-MUX problem, that demonstrates much faster convergence compared to its respective two-step update.

According to Lemma 2, the two-step update scheme is expected to improve the performance of the prediction error in the early stage of learning and the steady state. Although, it seems unfeasible to find an exact mapping between the frequency domain and time domain for a learning algorithm. This becomes even worse when the performance

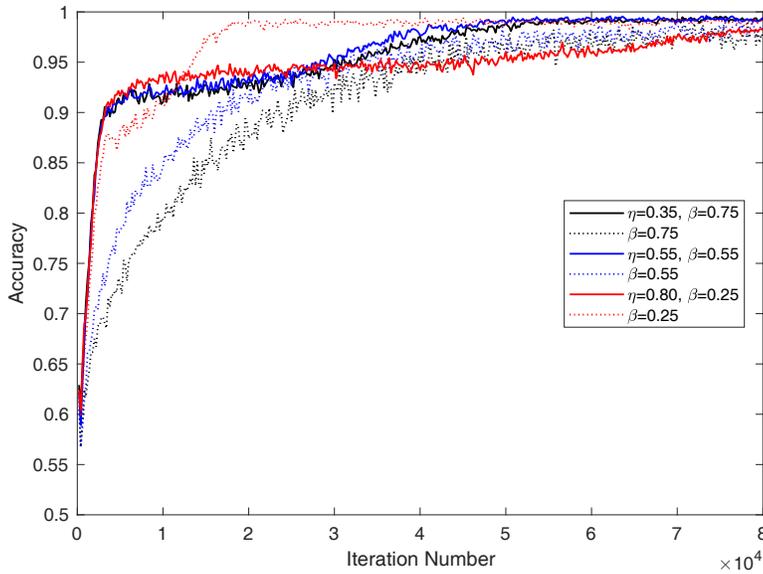

**Figure 2.** Comparison of learning accuracy for two-step (solid line) and one-step (dotted line) update rules for 6-MUX problem.

evaluation is problem independent, in other word no complexity measure of the problem is considered in the performance analysis. The 6-MUX problem is less complex compared to 11-MUX and 20-MUX problems with more inputs, as a result its performance has improved over the entire learning time. On the other hand, in 11-MUX the problem complexity influences the expected improvement such that the effective range (namely low frequency and high frequency ranges) of the proposed update is different than the 6-MUX problem. More specifically, for the case of  $\eta = 0.80$ ,  $\beta = 0.25$  the effect of two-step update rule vanishes faster than other combinations of the learning rates. Therefore, the one-step update scheme outperforms the proposed update rule. The 20-MUX problem behaves as expected for all combinations of learning rates and the entire learning time.

According to the experiments, the fact that the algorithm tends to converge faster, suggests the idea that the proposed method relatively supports those classifiers with correct actions which tend to be accurate in two consecutive appearances in the action set. This is an extra pressure toward evolving accurate solutions.

## 6. Conclusions and Future Work

In this work, a novel two-step Markov update scheme for XCS classifier systems and mathematical representations for rules to update

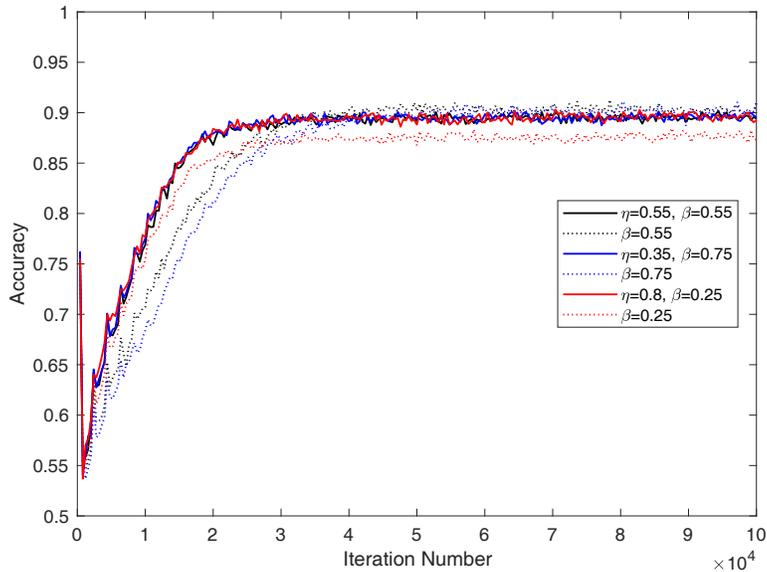

**Figure 3.** Comparison of learning accuracy for two-step (solid line) and one-step (dotted line) update rules for 11-MUX problem.

the classifier parameters using discrete-time dynamical systems theory are presented. The stability and convergence of the two-step update rules are analyzed. The frequency domain analysis for classifier parameters has been provided. We also presented the robustness and performance improvement of the XCS algorithm employing the two-step update rule using numerical experiments. The implementation cost includes adding four float type variables for each macro classifier and some arithmetic calculations, while its computational complexity and algorithm run time is almost the same. We have shown that using a non-Markov update contributes to faster learning and more accurate training at steady state.

Thus far, our analysis has been carried out independent of problem size and generality of classifiers, which may substantially impact XCS performance. In future work, the authors will address these issues and investigate their effects on algorithm dynamics as well as, the performance of the algorithm will be studied with real-world problems.
